Abstract

Carotenoids, such as lutein and β-carotene are generally recognized as antioxidants. However, only β-carotene has the pro-vitamin A activity. This study determined lutein and β-carotene in Asian leafy vegetables using reversed-phase high pressure liquid chromatography (HPLC). The selected samples were Chinese mustard (Brassica juncea var. rugose), water spinach (Ipomoea aquatic), Chinese spinach (Amaranthus tricolor), coriander (Coriandrum sativum), Chinese flowering cabbage (Brassica parachinensis), Chinese broccoli (Brassica oleracea albovabra) and Chinese white cabbage (Brassica chinensis). Carotenoids were extracted from samples into 5% (w/v) calcium carbonate and acetone. The extracts were then concentrated at 4 °C and filtered prior to HPLC analysis. The recoveries for β-carotene and lutein were 132% and 100%, respectively. The coefficient of variation for inter-variability study was < 3.8% and for intra-variability study < 11%. The range of β-carotene in the selected vegetables was 1974-6604 µg/100 g (wet weight basis), or 329-1101 µg/100 g retinol equivalent (RE). Measured lutein contents were between 694-5919 µg/100 g. Chinese broccoli had the highest pro-vitamin A activity (1101 µg RE per 100 g). The β-carotene data reported here was useful for estimating the pro-vitamin A intake from consuming the Asian leafy vegetables.

Introduction

Carotenoids are lipid-soluble pigments occurring naturally in plants. There are over 700 known carotenoids, including xanthophylls and carotenes [1]. While xanthophylls (e.g. lutein and zeaxanthin) contain oxygen in their molecules, carotenes, such as α-carotene and lycopene, contain only hydrocarbon without any oxygen. The main carotenoid found in Chinese vegetables is β-carotene and a value greater than 1000 µg/100 g can be considered as a good source of vitamin A [2]. Human bodies are able to transform dietary carotenoids to biologically active vitamin A, for example retinol. However, not all carotenoids have this pro-vitamin activity. One retinol equivalent (RE) is commonly used to express the biological activity from various carotenoids, where one RE corresponds to either 6 µg dietary β-carotene or 12 µg other dietary pro-vitamin A [3]. Vitamin A is essential for normal growth and development, immune system function and
vision. Foods rich in carotenoids can be sourced from carrots, pumpkin, dark green leafy vegetables, eggs and fish [4]. In Australia, as the food choices widen, Asian leafy vegetables become mainstream and they conveniently can be purchased from any supermarket. Traditional Asian vegetables, such as bok choy (Brassica rapa subsp. Chinesis) and kangkong (Ipomoea aquatica), are therefore no longer considered exotic [5].

In solutions, carotenoids are sensitive to light, heat, acid and oxygen, thus making them susceptible to oxidation and isomerization. For this reason, extraction of carotenoids from food matrices must be carried out rapidly and efficiently to minimize any degradation loss. High performance liquid chromatography (HPLC) interfaced with a photo diode array detector has been widely used for quantitation of carotenoids in various food matrices [1]. This study employed HPLC to determine the contents of β-carotene and lutein in selected Asian leafy vegetables, and lycopene in tomato. Initially, the limits of detection and quantitation, intra-variability and inter-variability studies, accuracy, and recovery were assessed to validate the HPLC method used for quantitation.

Materials and Methods

Chemicals

Carotenoid standards: β-carotene (C4582), lycopene (L9879), and lutein (07168) were purchased from Sigma-Aldrich (Sydney, Australia). All solvents used were of HPLC-grade (Sigma-Aldrich, Sydney, Australia). Purified water (conductance ≤ 0.1 µS/cm) was sourced from a Milli-Q system (Millipore, Bedford, MA, USA).

Collection and preparation of samples

For carotenoids determination, Asian leafy vegetables, such as Chinese mustard (Brassica juncea var. rugosa), Chinese spinach (Amaranthus tricolor), coriander (Coriandrum sativum), water spinach (Ipomoea aquatica), Chinese flowering cabbage (Brassica parachinensis), Chinese broccoli (Brassica oleracea albovaglabrata) and Chinese white cabbage (Brassica chinensis) were obtained in July-August 2014. Each individual sample was a composite sample of the same vegetable acquired from 3 different stores across Sydney (Lakemba, Campsie, Belmore and Kingsford). On the day of purchase, the vegetables were washed, dried and cut into small pieces. The vegetables were then homogenized in a kitchen blender (Breville, Sydney, Australia) and stored at -80 °C freezer until further analysis. Freeze-dried ‘oxhart’ tomato (Lycopersicon esculentum) was selected as a control sample, to monitor the reproducibility of the experimental data. Samples were processed under UV-free light to minimise carotenoids degradation.

Carotenoids extraction

Extraction of lutein, β-carotene and lycopene was carried out according to García-Plazaola (1999) with minor modifications. Samples (0.25 g, in duplicate) were initially placed in a mortar and ground into fine powder, while liquid nitrogen was decanted to the samples. Afterwards, 1 mL 5% (w/v) calcium carbonate and acetone were added before the liquid nitrogen fully evaporated. An additional 1 mL of acetone was pipetted to the pestle and mortar to collect the remaining ground vegetables and the mixture was aliquoted into the same tube [6]. Samples were centrifuged at 10,000 g for 10 mins at 4 °C (Thermo-Fisher, Sydney, Australia). Afterwards, the supernatants were concentrated to complete dryness at 4 °C using a Centrivap (Labconco, Kansas City, MO, USA). Prior to analysis, samples were resuspended in 1 mL of the mobile phase, vortexed and transferred into 0.2 µm eXtreme filter vials (Thomson, Oceanside, CA, USA).

To assess the accuracy of the method, β-carotene in the certified reference material (BCR-485 mixed vegetable) obtained from the Institute for Reference Materials and Measurements (Geel, Belgium) was determined. Additionally, the accuracy was verified by standard addition curves; for this purpose, increasing concentrations of standard solutions were added to Chinese white cabbage samples at the start of extraction and then analysed. The extraction efficiency was determined by spiking tomato samples (in duplicate) with known concentrations of carotenoids and then the recovery (%) was calculated. Samples (n = 8) were prepared simultaneously on the same day and analysed in the same run to assess the intra-day variability. The inter-day variability study was evaluated by repeated carotenoids extraction and analysis on three different days.

HPLC analysis

The HPLC system (Shimadzu LC-20AD series, Kyoto, Japan) used in this study was equipped with a photo diode array detector (SPD-M20A). The HPLC method was adopted from García-Plazaola and Becerril [6] with slight modifications. The aqueous mobile phase (solvent A) consisted of acetonitrile (84%), methanol (2%) and pre-filtered Tris buffer (0.1 M pH 8, 14%). The organic mobile phase (solvent B) contained methanol and ethyl acetate (68:32). The gradient started with 100% of solvent A before it was ramped up to 100% solvent B within 12 mins and kept for the next 6 mins. The initial condition (100% solvent A) was achieved in 1 minute and the column was re-equilibrated for 6 mins. Carotenoids were separated using a C4 column (Waters Nova-Pak, 3.9 x 150 mm, 5 µm) in a 25 mins run. The flow rate and injection volume were 1.2 mL/min and 15 µL, respectively. The chromatogram was monitored at visible wavelengths and the signal intensities detected at 450 nm were used for quantitation.

Standard calibration solutions

Stock standard solutions (100 µg/mL) were prepared by dissolving 1 mg of β-carotene, lycopene and lutein in the mobile phase, sparged with nitrogen gas and stored in the Eppendorf tubes in a -80 °C freezer. Working standard solutions were freshly diluted with the mobile phase on the day of use. The concentrations of lutein and β-carotene used for the calibration curves ranged from 1.0 to 33 µg/mL, and for lycopene between 1.0 to 12 µg/mL.

Results and Discussion

The peaks of lutein, lycopene and β-carotene were identified based on their retention times and the characteristic
visible absorption spectra [6]. The spectrum of each standard and the peaks are displayed in Figure 1. The parameters assessed for the method validation were limit of detection, limit of quantitation, inter-day and intra-day variability studies, recoveries, and accuracy.

![Figure 1: The peaks of lutein and β-carotene from standards (A) and a vegetable sample (B), and their respective absorption spectra.](image)

The carotenoids standard solution (0.5 µg/mL), detected at a signal to noise ratio 1:6, was set as the limit of detection (200 µg/100 g). The limit of quantitation was 400 µg/100 g (signal to noise ratio 1:11). Standard calibration curves for both analytes were linear over the range 400-13200 µg/100 g β-carotene ($r^2 = 0.994$) and 400-13200 µg/100 g lutein ($r^2 = 0.999$). The coefficients of variation (CV) for intra-day variability study were 6% and 11% for lutein and β-carotene, respectively. The CV for β-carotene presented here was comparable to a previous finding (4.6-10.5%) for measuring fruits and vegetables samples [7]. In term of inter-variability study, the CV for β-carotene was 3.8% and for lutein 3.6%. The recovery was higher for β-carotene (132%) than for lutein (100%) and lycopene (85%); the result suggested that lutein and β-carotene were efficiently released from the plant matrix and there was a minimum degradation loss occurred during sample preparation and analysis. Accuracy of the method was tested by analysis of BCR-485 and plotting the standard addition curves. The analysed β-carotene value (21.9 ± 0.47 µg/g) in BCR-485 was within the certified value (23.7 ± 1.5 µg/g). Lutein and β-carotene standard addition curves were both linear ($r^2 = 0.961$ for β-carotene and $r^2 = 0.964$ for lutein), thus confirming the accuracy of the method.

Quantification of Asian leafy vegetables

Carotenoids values presented in this study were expressed in µg/100 g wet weight basis (WWB). Mean moisture content in the vegetable samples was 96.4%. It has been reported that cooking methods, such as microwaving, 9 mins of boiling, steaming, and stewing does not significantly have an effect on lutein and β-carotene in green vegetables [8]. Other studies also found that β-carotene increases after boiling, stewing, steaming and pressure steaming of broccoli [9], in boiled and steamed courgettes/zucchini (*Cucurbita pepo* L.) and broccoli [10]. While boiling preserved β-carotene and lutein in leafy greens [11], 1 hour boiling significantly lowers the levels of lutein and β-carotene [8]. Cooking releases β-carotene from the plant cell wall and from its protein bound complex [9, 12].

Based on this premise, lutein and β-carotene measured in the raw vegetable samples were comparable with their respective cooked samples. The range of β-carotene in the selected samples was between 1974-6604 µg/100 g or 329-1101 µg RE (Table 1). The β-carotene contents measured in Chinese spinach (2524 µg/100 g) and Chinese white cabbage (2546 µg/100 g) were comparable with values reported in the previous Australian study, 2000 µg/100 g and 2200 µg/100 g, respectively [13]. Chinese flowering cabbage contained 4142 µg β-carotene per 100 g; this was higher than documented earlier, 2300 µg/100 g [13]. The discrepancy in the β-carotene values was attributed to different extraction protocols used for the studies. In our study, only liquid-liquid extraction was carried out, while in the previous study a combination of liquid-liquid extraction and saponification [13]. Also, other factors, such as analytical errors and the intrinsic difficulty in carotenoids analysis, have to be considered in generating the carotenoids data [14]. The highest β-carotene, 6604 µg/100 g, was determined in Chinese broccoli, and the lowest, 1974 µg/100 g, in Chinese mustard samples (Table 1). Overall, the levels of β-carotene measured here were higher than earlier findings [2]. A plausible reason for this was due to a degradation loss occurs during a lengthy sample preparation, which leads to low measured carotenoids values [15]. Additional factors affecting the carotenoids contents are cultivar/variety, analysed part of the plants, stage of maturity, climate/geography, harvesting and post-harvest handling and processing and storage [14]. Another explanation for the discrepancy in carotenoids contents would be due to season x variety interactions; flowering cabbage harvested in dry season contained higher β-carotene (96000 µg/100 g, dry weight basis) than those harvested in wet season [16]. On the other hand, mean β-carotene contents in Chinese broccoli collected in wet season is reported to be twice higher than those harvested in dry season [9]. Lower carotenoid contents in the wet season could possibly be due to reduced carotenoid synthesis under high temperatures or increased plant use of carotenoids as photo-protectants under high light intensities [17]. Currently, the carotenoids levels in some Asian leafy vegetables displayed in the Australian Nutrient Table (NUTTAB) are obtained from a 1984’s study. Our experimental data provided a valuable update on β-carotene...
levels from a more recent collection of vegetables.

Generally, the lutein content in Asian leafy greens is greater than β-carotene [16]. The range of lutein in the vegetables samples was between 694 and 5919 µg/100 g, where lutein was lowest in white cabbage and highest in coriander. Measured lutein in the coriander sample was higher than β-carotene, which is consistent with a reported value in Taiwanese coriander [11]. According to USDA National Nutrient database, white cabbage contains 48 µg lutein and 190 µg β-carotene per 100 g [18]; both values are much lower than our results. Lutein measured in the Chinese broccoli (3917 µg/100 g) was also similar to those sample obtained in the Philippines, 3700 µg/100 g [19].

Standard reference materials and certified reference materials are preferably analysed in every batch of analysis [20]. However, this approach is not cost-effective for routine analyses [20]. For this reason, we used freeze-dried ‘oxhart’ tomato as the in-house reference material, similar to other studies [21, 22]. Measured lycopene in freeze-dried tomato sample was 2271 µg/100 g and was lower than β-carotene (4123 µg/100 g). Studies show that lycopene in fresh tomato (per 100 g) is higher than β-carotene; raw tomato contains 3100 µg lycopene and 660 µg β-carotene [21]. Graça-Dias et al. also found that tomato has 2300 µg lycopene, which is greater than β-carotene (390 µg/100 g). Differences in carotenoids contents of tomatoes are not uncommon in the literature. The carotenoids contents vary considerably even within the same varieties, while other factors including maturity, soil and light intensity play also important roles [22]. Additionally, there are qualitative and quantitative differences in any given food due to factors such as cultivar/variety, maturity at harvest, climate/geographic site of production, season, part of the plant utilized, conditions during agricultural production, post-harvest handling, processing and storage conditions [23].

**Conclusion**

The HPLC method validated in this study successfully determined lutein and β-carotene in Asian leafy vegetables, and lycopene in freeze-dried tomato. The data obtained in this study can be used to estimate the β-carotene contribution to dietary carotenoids intake, expressed in RE. The lowest β-carotene, 1974 µg/100 g, was measured in Chinese mustard, and consuming 100 g of this vegetable would contribute to 329 µg RE (Table 1). It can therefore be suggested that Asian leafy vegetables measure here had substantial pro-vitamin A activity owing to their β-carotene contents.
